Abstract. The northern margin of the Ligurian Basin shows notable seismicity at the Alpine front, including frequent magnitude 4 events. Seismicity decreases offshore towards the Basin centre and Corsica, revealing a diffuse distribution of low magnitude earthquakes. We analyse data of the amphibious AlpArray seismic network with focus on the offshore component, the AlpArray OBS network, consisting of 24 broadband ocean bottom seismometers deployed for eight months, to reveal the seismicity and depth distribution of micro-earthquakes beneath the Ligurian Sea.

20

Two clusters occurred between ~10 km to ~16 km depth below sea surface, within the lower crust and uppermost mantle. Thrust faulting focal mechanisms indicate compression and an inversion of the Ligurian Basin, which is an abandoned Oligocene rift basin. The Basin inversion is suggested to be related to the Africa-Europe plate convergence. The locations and focal mechanisms of seismicity suggest reactivation of pre-existing rift structures. Slightly different striking directions of faults in the basin centre compared to faults further east and hence away from the abandoned rift may mimic the counter-clockwise rotation of the Corsica-Sardinia block during ~20-16 Ma. The observed cluster events support the hypothesis of strengthening of crust and uppermost mantle during rifting related extension and thinning of continental crust.

1 Introduction

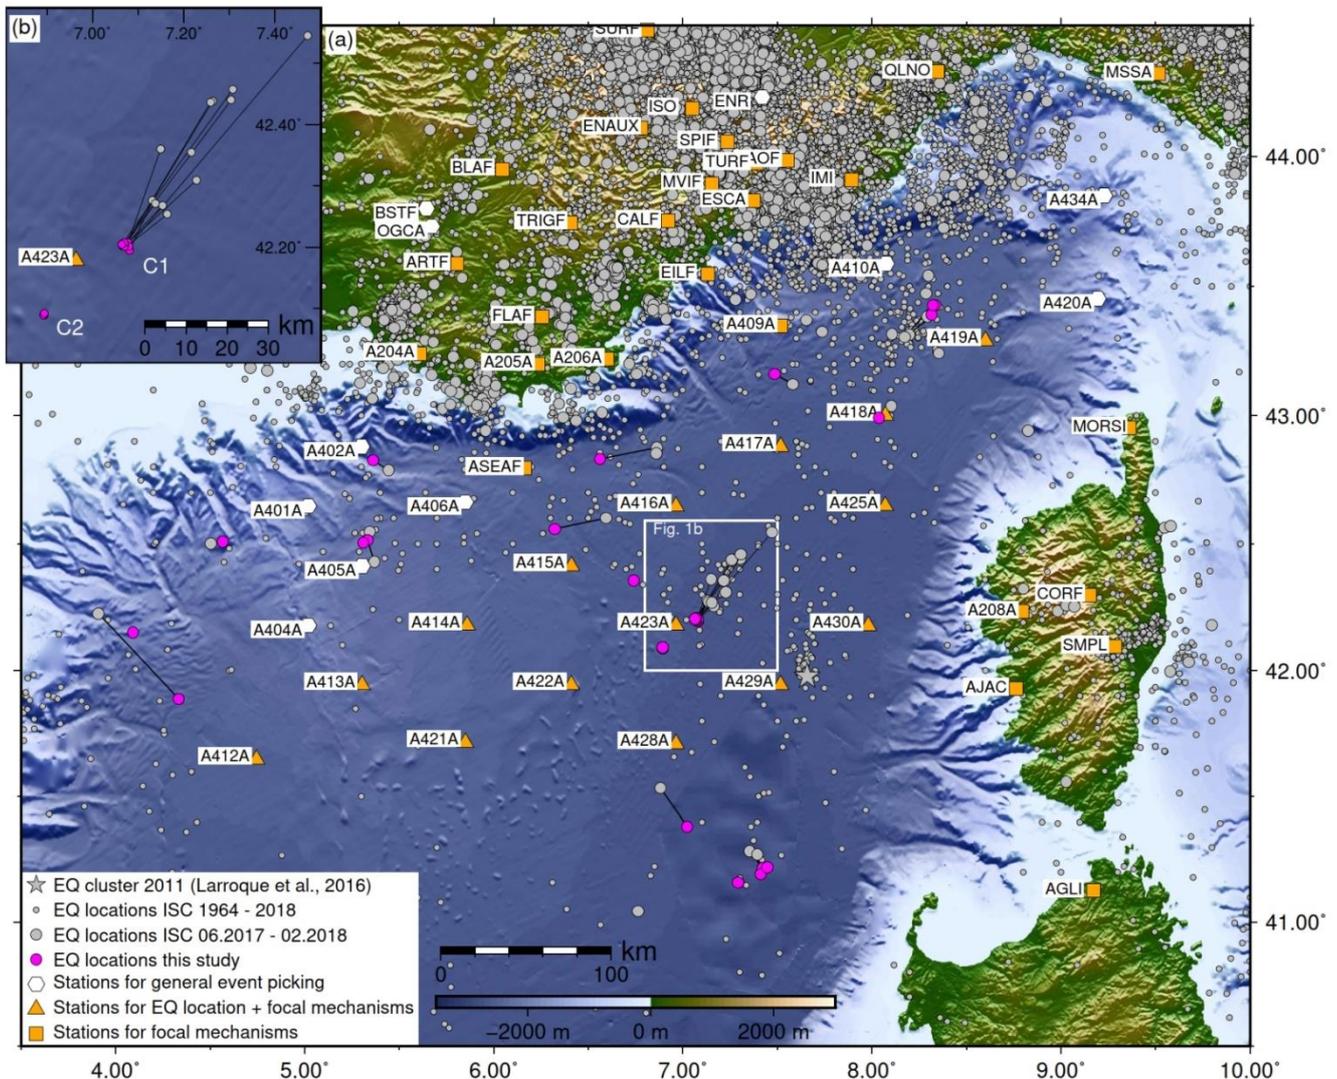

25

Earthquakes of magnitude 4 are frequently recorded in the Ligurian Basin, especially at the Ligurian margin at the junction between the southwestern Alps and the Ligurian Basin (hereafter named the Alps-Liguria junction) with maximum magnitudes of Mw 6 to 6.5, indicating a moderate seismic activity (Béthoux, 1992; Courboux et al., 2007; Béthoux et al., 2008; Larroque et al., 2012, 2016). Seismic activity is highest along the Côte d'Azur and the Ligurian coast and decreases towards the central basin and Corsica (Fig. 1). The Ligurian Sea formed during Oligo-Miocene times as a back-arc basin (Burrus, 1984; Rehault et al., 1984; Faccenna et al., 1997; Gueguen et al., 1998; Rosenbaum et al., 2002), but extension stopped ~16 Ma. Today, GPS

30

35

data do not show any significant shortening between Corsica and the northern rim of the Ligurian Sea (Nocquet and Calais, 2004), but compressive earthquakes occasionally occur. The interior of plates is, in general, predominantly aseismic (McKenzie and Parker, 1967). In these relatively stable tectonic regions, sparse seismicity may represent diffuse deformation and is commonly related to the reactivation of pre-existing fault planes (Zoback, 1992). In the Tyrrhenian Sea, the Africa-Europe convergence caused reactivation of pre-existing fault planes, revealing an inversion of the entire basin (Zitellini et al., 2020).

40

Figure 1: Topographic map of (a) the Ligurian Sea and (b) the area where the cluster events occur (GMRT data, Ryan et al., 2009). Grey circles mark the epicentres of earthquakes as observed in the ISC bulletin (Storchak et al., 2017). Magenta circles mark the epicentres of earthquakes within the Ligurian Basin observed in this study. Black lines connect locations of the same events found in both the ISC bulletin and this study.

Here, we report on local seismicity in the centre of the Ligurian Basin (Fig. 1a). We analysed two earthquake clusters (Fig. 1b) that were recorded by an amphibious seismic network operated in the framework of the European AlpArray initiative (Hetényi et al., 2018). The AlpArray OBS network, a long-term ocean bottom broadband seismometer (OBS) array, recorded ground motion continuously for 8 months. The deployment of long-term OBS enables robust source estimates of earthquakes far away from land stations. Nevertheless, observations from the land stations improved the estimate of fault plane solutions. The observed earthquake clusters and their depth distribution provide constraints on the crust and upper mantle rheology and provide insights into today's regional stress field.

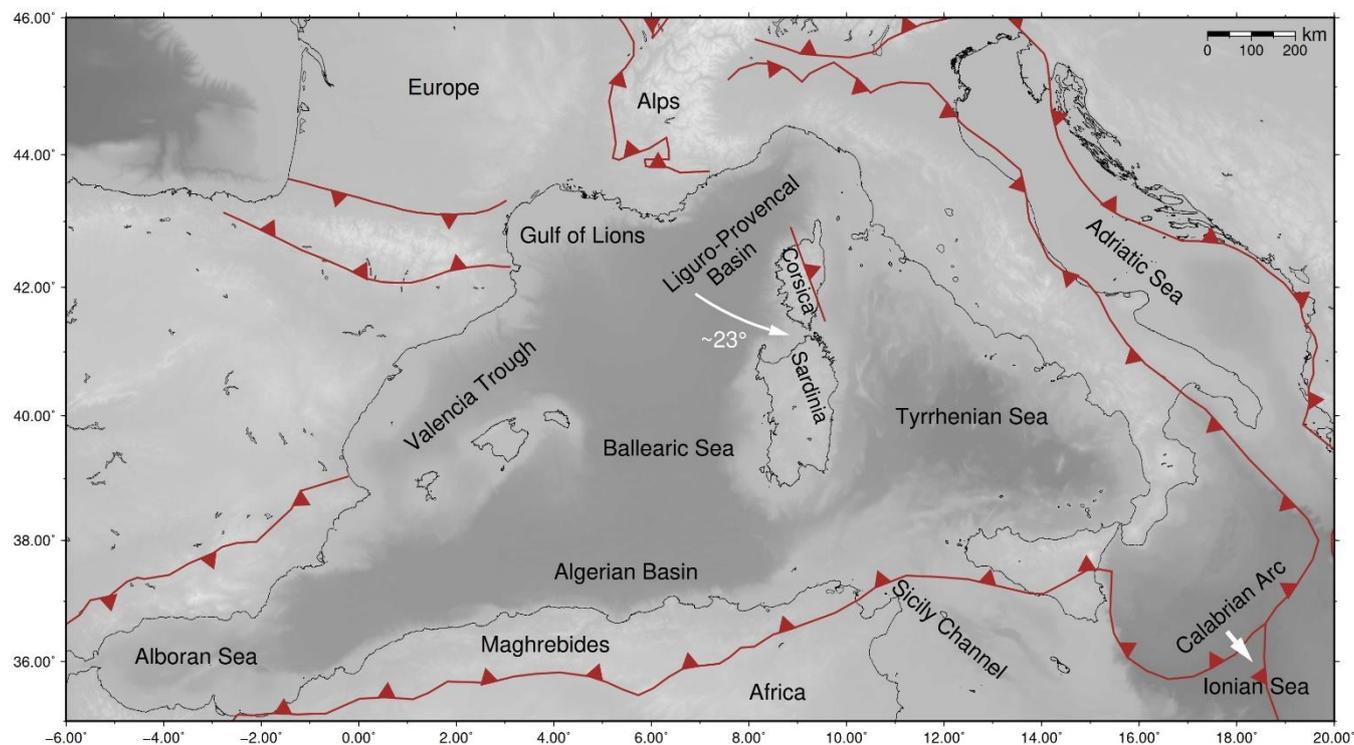

2 Geological and geodynamic setting

The Western Mediterranean, including the waters west of Apennines and Sicily, consists of several basins (Fig. 2) that formed from Oligo-Miocene times to the present (e.g. Burrus, 1984; Rehault et al., 1984). The geodynamic setting is controlled by the convergence of the African and Eurasian plates (e.g. Dercourt et al., 1986) and the rollback of the Apennines and Calabrian subduction zones (Jolivet and Faccenna, 2000). The fast rollback of the westward migrating Gibraltar arc and the eastward migrating Apennines arc played a major role in the opening of the Mediterranean sub-basins (Lamotte et al., 2000; Mauffret et al., 2004; Handy et al., 2010). The Ligurian Basin, opening ~30-16 Ma (Burrus, 1984; Bache et al., 2010), and the Alboran Basin, opening ~25-20 Ma (Faccenna et al., 2004), are the oldest basins in the Western Mediterranean. The Algerian Basin, opening ~16-8 Ma (Mauffret et al., 2004), and the Tyrrhenian Basin, opening ~8-0 Ma (Faccenna et al., 2001; Rosenbaum et al., 2002), are the youngest basins in the Western Mediterranean. In the latter two basins, geophysical and geological data clearly show that extension caused break-up and seafloor spreading (Nicolosi et al., 2006; Bouyahiaoui et al., 2015; Prada et al., 2016; Booth-Rea et al., 2018), while the Alboran Sea is a domain of extended continental crust modulated by arc magmatism (Booth-Rea et al., 2018; Gómez de la Peña et al., 2020). The Balearic Sea is floored by oceanic crust (Gailler et al., 2009; Afilhado et al., 2015; Moulin et al., 2015). However, the extent and nature of the oceanic domain towards the northeast into the Liguro-Provencal Basin remains debated.

The Ligurian Basin underwent a long-lasting phase of extension from Late Oligocene to Miocene (Rehault et al., 1984; Gueguen et al., 1998; Finetti et al., 2005), progressively opening from south to north. Based on magnetic and seismic data, oceanic spreading with unroofing of mantle material was proposed for the late opening period ~21-16 Ma (Le Douaran et al., 1984; Pascal et al., 1993; Contrucci et al., 2001; Rollet et al., 2002; Speranza et al., 2002). For the Ligurian Basin, which is the NE part of the Liguro-Provencal Basin, a recent analysis of a seismic refraction profile proposes that rifting failed before oceanic spreading initiated (Dannowski et al., 2020). The Corsica-Sardinia block underwent a counter-clockwise (CCW) rotation (Alvarez et al., 1973; Rehault et al., 1984; Speranza et al., 2002; Maffione et al., 2008) of ~23° over a short time ~20-16 Ma (Speranza et al., 2002) (Fig. 2). Extension in the Ligurian Basin ended ~16 Ma and continued afterwards in the Algerian and Tyrrhenian basins (Mauffret et al., 2004).

75 The Calabrian trench retreats further south-eastwards (Fig. 2, white arrow), however, recent seismological observations indicate that Tyrrhenian Sea opening ceased and the Africa-Eurasia convergence results in basin inversion at its southern rim (Zitellini et al., 2020). It is proposed that the major shortening caused by the convergence between Africa and Europe is accommodated in the Maghrebides ranges in North Africa (90-100%) and that the Ligurian Basin and the Corsica-Sardinia block are rigid (Nocquet and Calais, 2004; Béthoux et al., 2008; Nocquet, 2012). However, passive seismic studies observe signatures of compression in the Ligurian Basin (Béthoux, 1992; Baroux et al., 2001; Eva et al., 2001; Courboulex et al., 2007; Béthoux et al., 2008; Larroque et al., 2012, 2016). Moreover, active compressional structures were imaged in seismic reflection profiles (Bigot-Cormier et al., 2004) offshore the Ligurian coast. Along the Corsica margin, seismic reflection data do not image significant seismic ruptures that reached the surface since ~5 Ma, but earthquakes of M_L 5.5 and M_L 4.4 occurred in July 2011 offshore Corsica (Larroque et al., 2016) (Fig. 1, grey star). While the Ligurian margin is narrow and steep with a few listric normal faults, the Corsica margin is wider and several listric faults were imaged in seismic reflection data (Finetti et al., 2005). Within a short distance of 30-50 km, the crust-mantle boundary (CMB) deepens from ~15 km depth in the basin to ~25 km depth at the continental margins (Contrucci et al., 2001; Gailler et al., 2009; Dessa et al., 2011).

90 **Figure 2: Geographic and tectonic overview map with thrusts modified from Le Breton et al. (2020). The white arrows indicate the ~23° CCW rotation of the Corsica-Sardinia block during Miocene times (Speranza et al., 2002) and the trench retreat of the Calabrian Arc. GMRT data were used as background topography (Ryan et al., 2009).**

3 Data and results

The AlpArray OBS network consisted of 24 broadband OBS (Fig. 1) that continuously recorded ground motion for ~8 months (June 2017 to February 2018). The stations were deployed with a spacing of ~60 km using the French research vessel “Pourquoi Pas?” and recovered during research cruise MSM71 on the German research vessel “Maria S. Merian”. Data from two OBS
95 instruments types were used in our study: (1) German OBS, provided by the DEPAS pool and GEOMAR (Lobster type), equipped with a Trillium Compact 120 s seismometer and an HTI-04-PCA/ULF hydrophone recording on 6D6 KUM recorders with a sampling frequency of 250 Hz. (2) French OBS, provided by the IGP-INSU pool (BBOBS), equipped with a Trillium 240 s seismometer (T240) and a differential pressure gauge (DPG) recording at a frequency of 62.5 Hz. Additionally, land data (Fig. 1) were used from different regional permanent and temporary seismological networks: AlpArray (Z3), Italian
100 National (IV), French RESIF-RLBP (FR) and Mediterranean MedNet (MN).

3.1 Events, picking and location

During the long-term OBS deployment, 39 seismic events were detected within the Ligurian Basin excluding the Alps-Liguria junction zone (Fig. 1a, magenta circles). Our work focuses on two earthquake clusters in the centre of the Ligurian Basin, near OBS A423A (magenta circles in Fig. 1b; Table 1). The first cluster (C1) consists of 13 events that occurred from June to
105 November 2017 (Fig. 3a, blue bars). The second cluster (C2) consists of three events that occurred during one day in January 2018, about 25 km southwest of C1 (Fig. 3a, red bars). Two events (grey bars in figure 3a) had few observations and high uncertainties, they were not used in this interpretation. Two more small events were only observed at station A423A and were not further analysed (Fig. 3a, black bars). We show that a seafloor network could detect more events than those in the ISC catalogue (Tab. 1), whose magnitude of completeness is 2.2 in the region, but the four events (grey and black bars in Fig. 3a)
110 indicate that the AlpArray OBS station spacing is too large to render a more precise picture of the local seismicity.

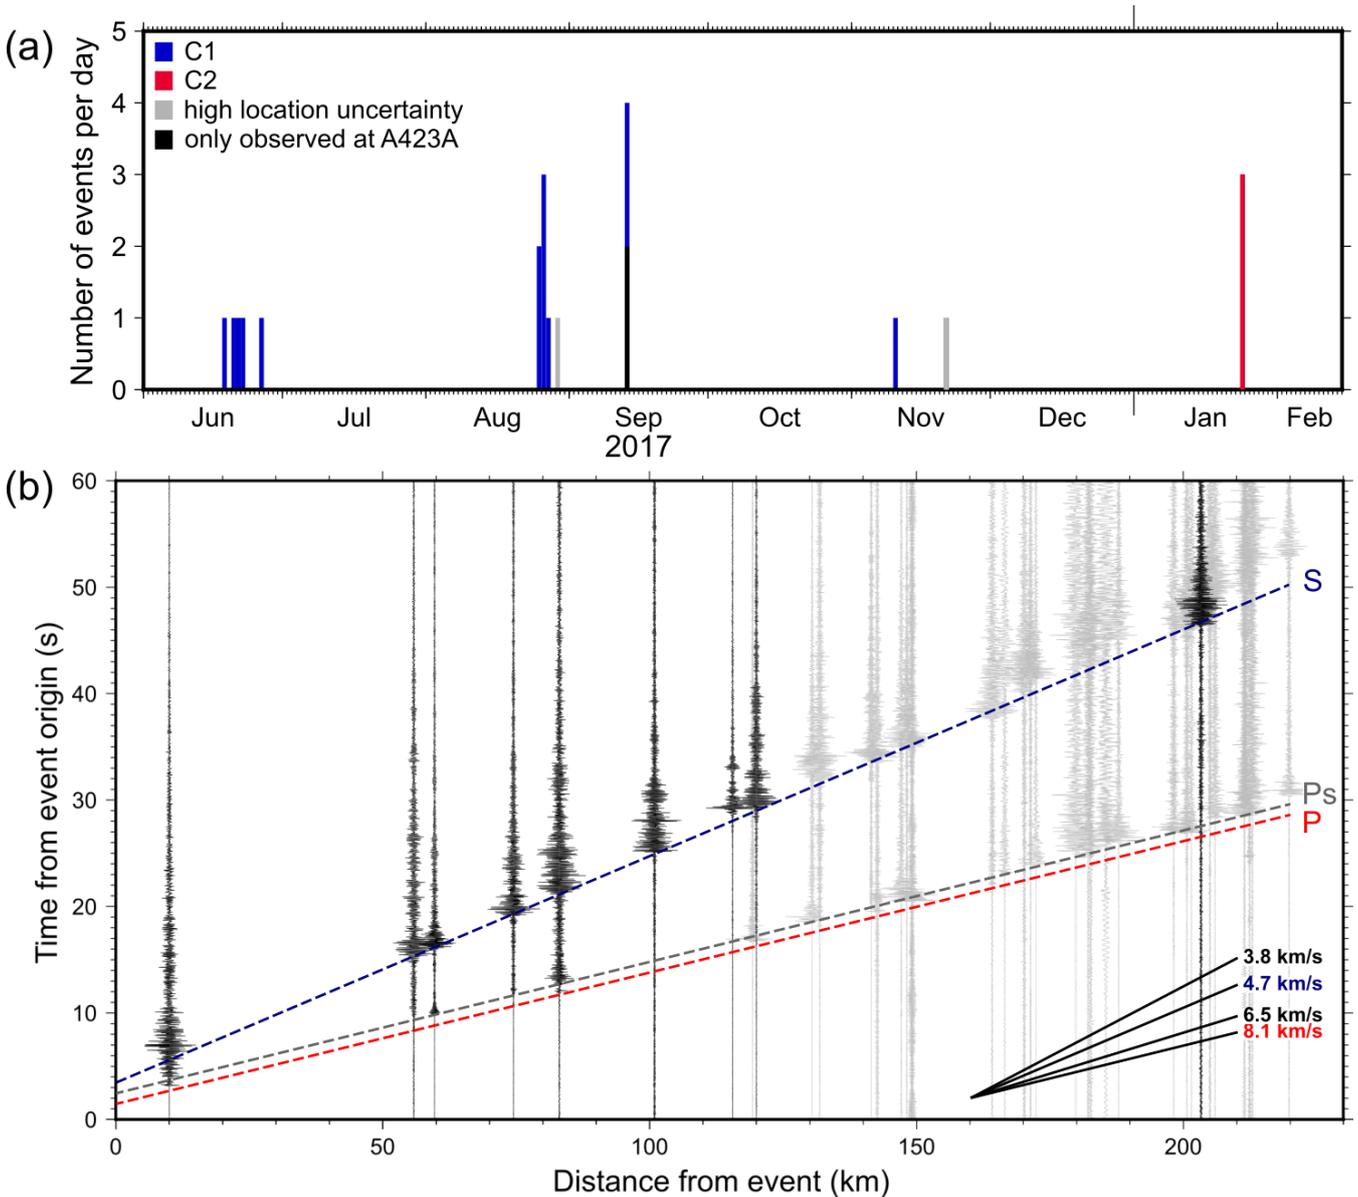

Initially, the ISC bulletin (Storchak et al., 2017) was used to detect seismic events in the AlpArray OBS data. The phases were picked manually on all stations plotted with orange triangles, orange squares and white hexagons in Figure 1b. Only the seismometer components were used in our analysis since the signal-noise ratio on most of the hydrophones was too low to identify local seismic events.

115 Three onsets predominated the observed events: the P-wave, a converted Ps-wave and the S-wave (Fig. 3b). The P-wave is weak in amplitude and followed by a stronger Ps-phase. Both phases indicate an apparent P-wave velocity (V_p) of ~8.1 km/s and they are separated by a nearly constant time difference of ~1 s. The S-wave phase has a high amplitude, compared to the P-onsets, and shows an apparent S-wave velocity (V_s) of ~4.7 km/s (Fig. 3b). The waveforms are highly coherent as shown for the vertical component of station A423A (Fig. 4a). Picking was done for the P-onset on the vertical component and for the
120 S-onset on the horizontal components using SEISAN (Havskov and Ottemoller, 1999).

Within cluster C1, two main families of waveforms are observed indicating a repeated activation of the fault. Family 1 was active in June 2017 and consists of events 2, 3, and 4. Family 2 was active at the end of August and again in September 2017

and consists of events 5 to 10, 12, and 13. Cluster C2 consists of a third waveform family, events 16 to 18. The coherency within the families is >0.8 .

125

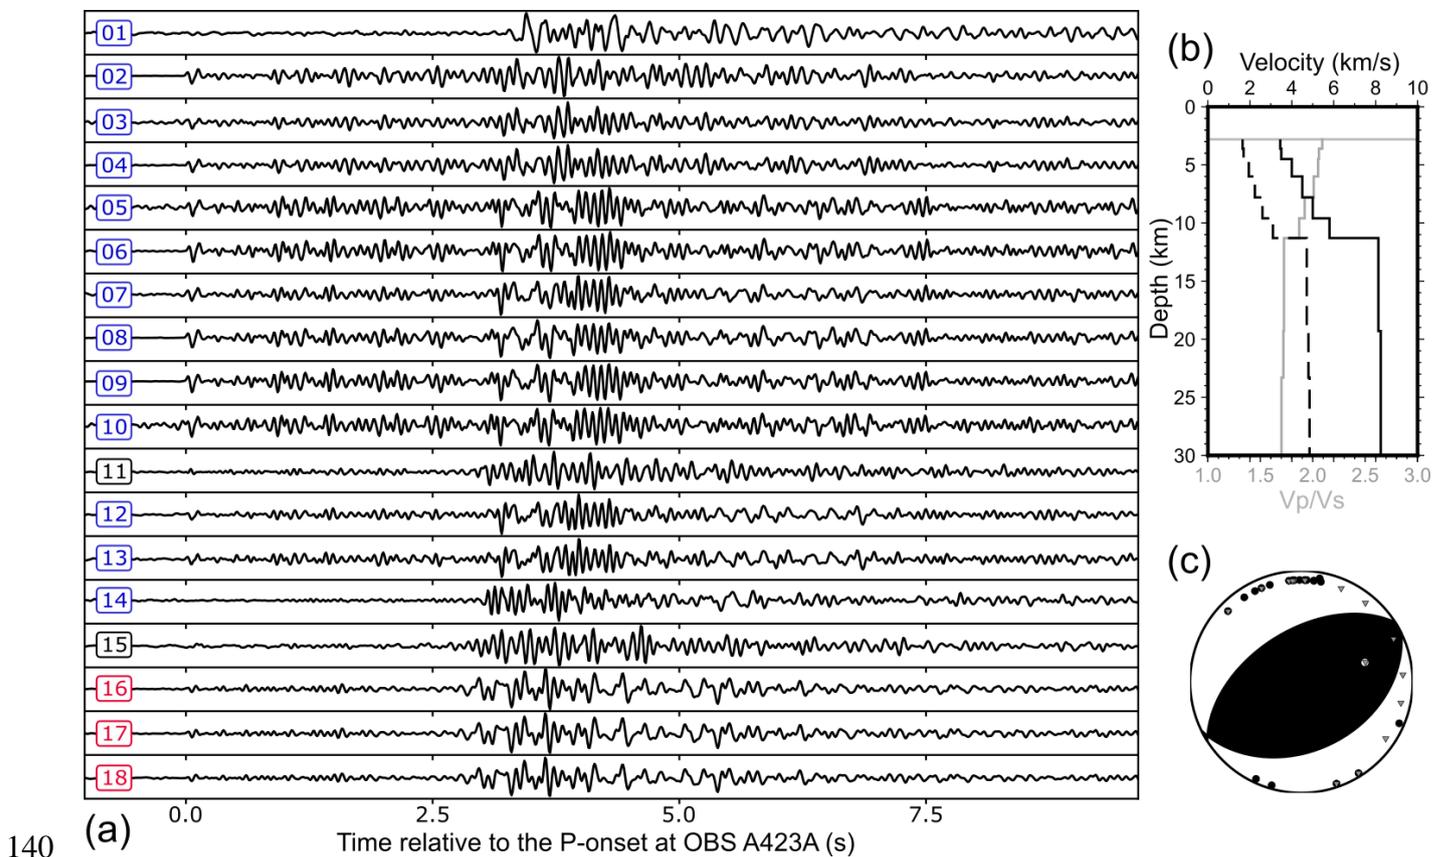

Figure 3: Panel (a) shows the temporal development of the cluster events in blue for C1 and in red for C2. Black events were only observed at A423A and not further analysed. Grey events were located with high uncertainties. (b) Waveforms of the strongest event of C1 (20.06.2017) displayed over offset. Black traces were used for EQ location. A weak P onset (red line) is observed, followed by a stronger Ps phase (grey line) ~ 1 s later. The S phase (blue line) is well visible at all stations. Apparent velocities of $V_p=8.1$ km/s and $V_s=4.7$ km/s are observed for the phase onsets.

130

We use only stations within the basin (orange triangles in Fig. 1) to locate the events. In this way, we can use a 1-D seismic velocity model for the basin and avoid errors introduced by the extreme topography and changes in crustal thickness near the

135 margins. We applied the 1-D velocity model (Fig. 4b) that is based on P-wave velocities from the seismic refraction profile p02 (Dannowski et al., 2020) (Fig. 5e). A V_p/V_s ratio of 2.0 at the seafloor and 1.87 above the CMB was assumed to convert V_p to V_s (Fig. 4b). The observed apparent velocities of mantle refracted waves P_n and S_n (Fig. 3b) were used as V_p and V_s for the uppermost mantle in the 1-D velocity models (Fig. 4b). After an initial event location, using SEISAN (Havskov and Ottemoller, 1999), events of the two clusters were relocated with hypoDD, a double-difference earthquake algorithm for relative relocations (Waldhauser and Ellsworth, 2000). Because our clusters containing only a few events and the background velocity model is well-constrained, we used hypoDD's singular value decomposition (SVD) solver.

140 (a) All observed cluster events recorded at station A423A, Z-component (bandpass filtered 2-20 Hz). The P-onsets are shifted so that they align at 0 s. (b) 1-D velocity models (V_p , solid line, V_s , dashed line, and V_p/V_s grey solid line) used to relocate the cluster events. (c) Focal mechanism of event 2, computed using the amplitude ratio of S_v/P (grey inverted triangles) and the wave polarisation (black dots for negative polarisation) determined at OBS and land stations.

145 Epicentres of events observed in both the ISC bulletin and our study, were compared. Pairs are connected by black lines in the seismicity map (Fig. 1). The epicentres based on the ISC bulletin are spread over a 50x20 km zone. In contrast, the same events located solely based on OBS data plot in a very narrow 3x3 km zone (Fig. 1b and 5b). Additional events with magnitude $M_L < 2$ were detected using the OBS; these events were also recorded by the land stations (Fig. 1) but their amplitudes were close to the noise level.

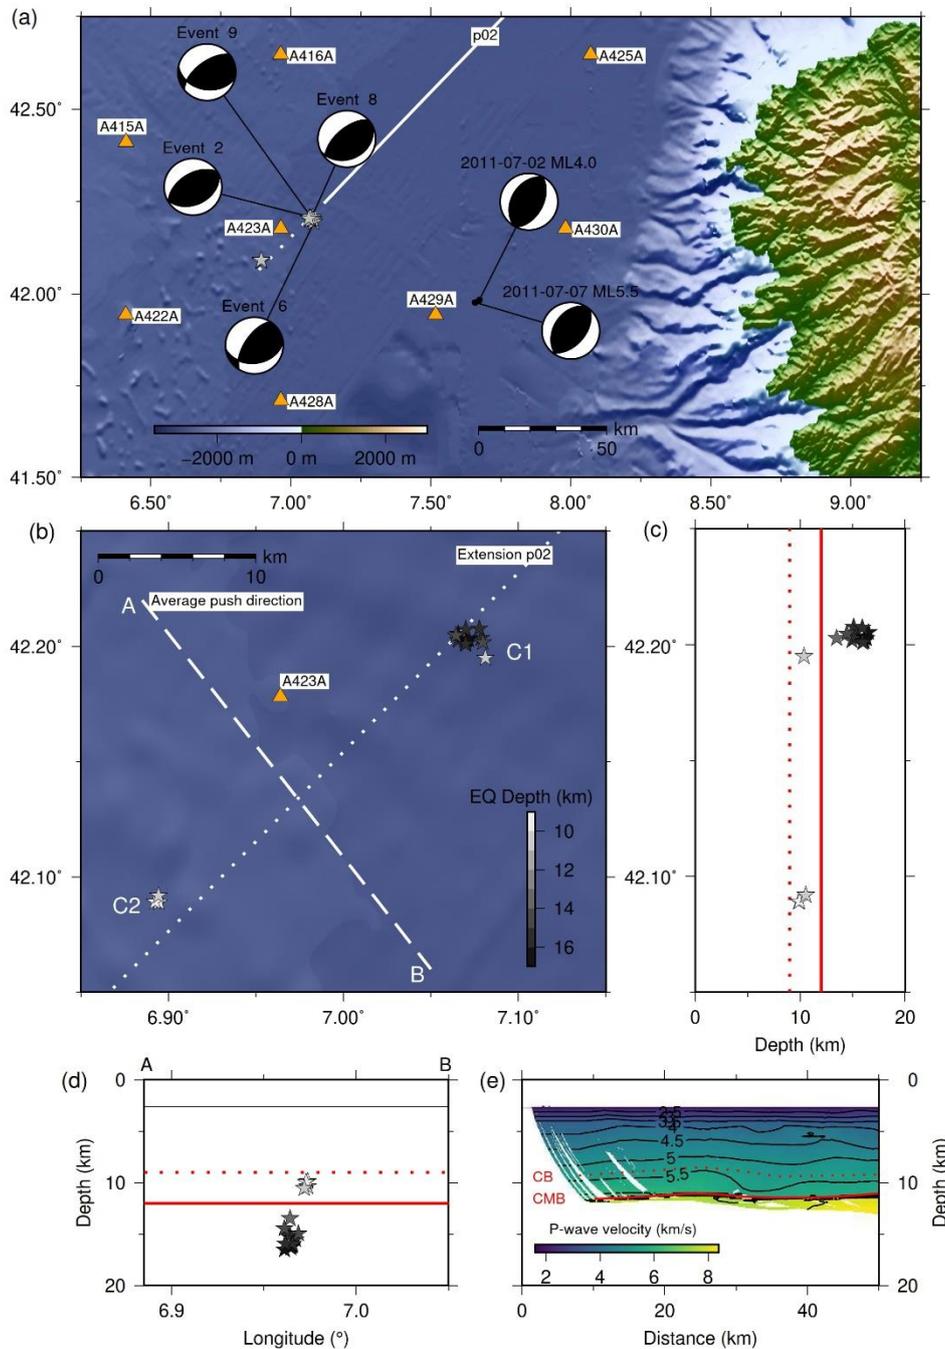

150 **Table 1: Epicentral locations and focal depths for the cluster events from hypoDD (depth below sea surface). Magnitudes and focal mechanisms were computed for events that show clear wave polarities.**

3.2 Focal mechanisms

155 To estimate fault plane solutions we used the stations shown in orange in figure 1. The station distribution provided a good azimuthal coverage for the Ligurian Sea. Additionally, the permanent station VSL in southern Sardinia (located outside the map of Fig. 1a) was used. The first motion direction of the P-wave was determined for on- and offshore stations where clearly visible. The amplitude ratio of P- and S-wave was determined on the vertical component at land stations only. The ocean bottom stations showed unusual small amplitudes for the P-wave compared to the S-wave, indicating systematic faulty recording. Polarity and amplitude ratios were used to derive the fault plane solution of events 2, 6, 8, and 9 (Fig. 4; Tab. 1) by means of the program FOCMEC (Snoke, 2003). In general, the events of cluster C1 show stronger amplitudes compared to C2. The four fault plane solutions of cluster C1 indicate thrust faulting (Fig. 4c and Fig. 5a). The arrivals from events of C2 were not of sufficient quality to calculate focal mechanisms.

160

165 **Figure 5: (a) Focal mechanisms of C1 cluster and two events in 2011 (Larroque et al., 2016). (b) Zoom into the map from panel a.**
 The white dotted line indicates the prolongation of seismic refraction profile p02 (white line in panel a) and the white dashed line
 170 represents the main horizontal direction of the pressure axis P as indicated by focal mechanisms. (c) Depth distribution of the cluster
 events from North to South. (d) Events projected on the dashed line A-B shown in panel b. The thin black line indicates the seafloor,
 the dotted red line is the crystalline basement (CB) and the solid red line is the crust-mantle boundary (CMB). (e) SW end of the
 seismic velocity model computed from seismic refraction profile p02 (Dannowski et al., 2020). Topography from GMRT data (Ryan
 et al., 2009).

4 Discussion

4.1 Basin inversion

Geodetic measurements in Corsica and Sardinia show residual velocities <0.5 mm/y with respect to stable Europe (Nocquet and Calais, 2004), which the authors use to conclude that the shortening at the Alps-Liguria junction, expressed in widely distributed low- to moderate-magnitude earthquakes, is a result of the ongoing CCW rotation of the Adriatic microplate, rather than a S-N motion of the Corsica-Sardinia block. Further, Larroque et al. (2016) observed an earthquake cluster in 2011 offshore Corsica (Fig. 5a) accompanied by events in 2012 and 2013 located in the same area, but they did not observe surface ruptures nor faults rupturing the Plio-Quaternary sediments in the epicentre area of the 2011 events. Inspired by their analysis, we studied the seafloor bathymetry in the C1/C2 region and observed no fault structure. Nor do pre-existing multi-channel seismic data map sufficiently large faults in the sedimentary strata. The C1 and C2 events are smaller than the 2011 events and occurred at similar focal depth. Thus, we assume that the rupture is entirely located within the lower crust and uppermost mantle and does not reach post-rift sediments. This suggests a long-term deformation without cumulating slip concentrated in one fault plane but rather distributed rupture areas.

Larroque et al. (2016) debated whether the 2011 cluster results from ridge-push forces of an oceanic spreading centre in the Ligurian Basin or a southward propagation of the deformation at the Alps-Liguria junction. They exclude the hypothesis of a spreading centre, since no spreading axis had been mapped. Our study corroborates this hypothesis, since clusters C1 and C2 are located in the basin centre and would be even closer to or at the proposed spreading axis and so ridge-push forces would be higher. Additionally, no spreading axis was mapped in more recent seismic studies and the LOBSTER seismic refraction profile p02 (Dannowski et al., 2020) proposes that rifting failed before seafloor spreading was initiated.

To summarise previous studies, sources for the regional compressional stresses could be: (1) Africa-Europe convergence, (2) CCW rotation of the Adriatic plate (Larroque et al., 2016), or (3) north-eastward motion of the Tyrrhenian Sea towards stable Europe (Nocquet, 2012). Geodetic stations in Northern Africa are still missing, excluding reliable constraints on plate motions based on geodetic measurements (Nocquet, 2012). The latest plate motion models (Nocquet, 2012; Le Breton et al., 2017, 2020; van Hinsbergen et al., 2020) are based on seismicity and other geophysical and geological information and indicate that the majority (90-100%) of Europe-Africa convergence is accommodated in the Maghrebides. The Ligurian Basin and the Corsica-Sardinia block are seen as rigidly attached to stable Europe (Nocquet, 2012).

The epicentres of cluster C1 were located in the uppermost mantle (one event in the lower crust) and their mechanisms are thrust faulting (Fig. 5), while the epicentres of cluster C2 were located in the lower crust, above the CMB. The 2011 events were also thrust faulting events which occurred in the crust and uppermost mantle (Larroque et al., 2016), roughly 50 km E-SE of clusters C1 and C2. If we project C1 and C2 on line A-B that follows the push direction of the thrust events, they map in a slightly tilted vertical plane dipping south-eastwards (Fig. 5d). Independently of the source of regional stresses, we interpret the C1 and C2 clusters and the 2011 cluster as a result of basin inversion and hence a reactivation of the Oligocene-Miocene rifting structures. The basin inversion in the Ligurian Basin is characterised by a diffuse distribution of rupture areas

of small size spread over a wide area in the basin centre. Shortening in the Ligurian Basin can be taken up by these remaining
205 rifting structures, enabling the closure of the Ligurian Basin. Our results show that today's observed seismicity based on land
stations underestimate the number of earthquakes in the Algerian and Ligurian basins. Reactivation of pre-existing and often
rifting-related fault planes was observed in other areas, for example in the Tyrrhenian Sea (Zitellini et al., 2020), in the Gulf
of Cadiz (Grevemeyer et al., 2016) and in northern Honshu, Japan (Kato et al., 2009). Therefore, like the Tyrrhenian Sea
(Zitellini et al., 2020), the Ligurian Sea may have entered a stage of basin inversion.

210 **4.2 Implications on rifting history**

While earthquakes are spread over the entire Ligurian Basin (Fig. 1), the C1 and C2 events cluster within small areas. C1 and
C2 are separated by ~25 km in a NE-SW direction, suggesting that both clusters may originate from the same fault zone. The
focal mechanisms of cluster C1 are similar to the 2011 events (Larroque et al., 2016). In detail, we observe a difference of
~15° between the striking direction of the fault planes of C1 and the striking direction of the 2011 events. As discussed before,
215 we interpret the three clusters as caused by the reactivation of Oligocene-Miocene rifting structures. Normal faults that were
created during the extensional phase are turned into reverse faults and their strikes are those of the normal faults during the
extensional phase. Since the 2011 events are located more to the southeast, they represent an older phase of rifting compared
to C1 and C2. Thus, we speculate that this difference in strike might be connected to the 23° CCW rotation of the Corsica-
Sardinia block compared to stable Europe that took place between ~20-16 Ma (Speranza et al., 2002; Le Breton et al., 2017).

220 **4.3 Rheology of crust and uppermost mantle**

Earthquakes in continental domains normally occur in the upper crust, while the lower crust is relatively aseismic and
earthquakes are rare in continental mantle lithosphere (Maggi et al., 2000). Whereas earthquakes certainly occur in oceanic
crust and mantle lithosphere (Wiens and Stein, 1983). Similar to oceanic lithosphere, Maggi et al. (2000) suggest that the
strength of continental lithosphere is controlled by the temperature structure and the amount of water in the formation and
225 resides in one seismogenic layer within the crust. They propose that continental mantle lithosphere is relatively weak, and
thus, aseismic. However, episodes of rifting may affect crustal and mantle rheology.

Rifting models suggest that the rheology of the continental domain changes during extension at non-volcanic rifted margins
(Pérez-Gussinyé and Reston, 2001). With increasing stretching, the portion of the crust that becomes brittle increases.
Stretching of the lithosphere will cause lower temperatures at the crust-mantle boundary, which in turn, will strengthen the
230 entire crust. When the entire crust is brittle, faults can cut through the crust into the mantle and act as fluid pathways, a pre-
condition to initiate mantle serpentinisation during rifting (Pérez-Gussinyé and Reston, 2001). The serpentinites create a weak
base of the crust, enabling detachment along the CMB and crustal fault block rotation. The serpentine thickness increases with
increasing rift duration until the final break-up of the continent (Pérez-Gussinyé and Reston, 2001).

235 The cluster events discussed here are interpreted to reflect pre-existing normal faults generated during rifting. We recognise a
good relationship between our data and the rifting model of Pérez-Gussinyé and Reston (2001), suggesting that the entire
continental crust may have evolved into a brittle domain during extension. The C1 events at mantle depths are more puzzling.
Earthquakes within continental mantle lithosphere were also observed in the Gulf of Cadiz, in the southern Iberian old Jurassic
mantle lithosphere (Grevemeyer et al., 2016). An explanation could be that during extension, mantle material moves closer to
the surface than before stretching, causing mantle temperatures to decrease (Sandiford, 1999). Thus, the mantle in the basin
240 centre might become stronger and more brittle than the surrounding mantle (Sandiford, 1999). Such a scenario is supported by
cluster C1 occurring in the uppermost mantle and supporting a low V_p/V_s -ratio of 1.72 (Fig. 4b). The crustal structure in the
vicinity of clusters C1 and C2 is well imaged by the LOBSTER seismic refraction profile p02 (Dannowski et al., 2020), which
provides no indication of a high amount of mantle serpentinisation at its southern end. A high sedimentation rate during rifting
may have prevented water from penetrating down to the mantle (Rüpke et al., 2013), minimising serpentinisation. However,
245 water may have occasionally reached the mantle, causing serpentinisation around some rift-related faults and weakening the
mantle locally (Pérez-Gussinyé and Reston, 2001), possibly enabling the reactivation of rifting-related normal faults as reverse
faults.

High heat flow (>100 mW/m²) in the Ligurian Basin (Pasquale et al., 1994) may contradict a cool CMB at the basin centre.
However, Hansen and Nielsen (2002) showed that a combination of a very thick sedimentary cover (>8 km), extremely low
250 conductive sediments (<1.5 W/mK) and very shallow and localised crustal radiogenic heat production allow for a temperature
maximum at the CMB beneath the basin centre. The thick sedimentary cover in the Ligurian Basin (up to 7 km, Schettino and
Turco, 2006) might cause thermal blanketing, reducing the lithospheric heat loss, in line with the observed high heat flow
values in the basin centre compared to the margins.

5 Conclusions

255 The entire Ligurian Basin is characterised by sparse but wide-spread micro-earthquakes of magnitude <3 . A 2017-2018 ocean-
bottom seismometer deployment recorded two earthquake clusters that show thrust faulting mechanisms, supporting a model
of inversion of the Ligurian Basin, in which the basin's centre is under compression and stresses are taken up by reactivated
faults in the crust and uppermost mantle. Compressional forces are probably related to Africa-Europe plate convergence. The
location of the cluster events and their focal mechanisms indicate that they occurred in reactivated pre-existing rift structures.
260 Slightly different striking directions of faults in the basin centre compared to faults further east and hence away from the
abandoned rift may mimic the counter-clockwise rotation of the Corsica-Sardinia block during ~ 20 -16 Ma. In general,
observations of earthquakes in continental mantle lithosphere are rare. Here, they reveal a strengthening of the crust and
uppermost mantle during rifting and they support the interpretation that rifting failed in the northern Ligurian Basin. Additional

265 data from an array of more densely spaced OBS would be needed to obtain a more complete picture of local seismicity in the
basin centre.

Acknowledgements

We thank the captain and crew of the R/V Maria S. Merian (cruise MSM71, 7-27 February 2018) and the R/V Pourquoi Pas? (AlpArray cruise, 14-26 June 2017). We thank the cruise participants of both cruises for their efforts. OBS were provided by the DEPAS pool, GEOMAR, and IGP-INSU pool. The deployment of the German component of the AlpArray seismic network (AASN) was funded by the LOBSTER project that is part of the German Priority Programme SPP2017 4D-MB. The deployment of the French component of the AASN was funded by the AlpArray-FR project of the Agence Nationale de la Recherche (contract ANR-15-CE31-0015). We also thank the AlpArray Seismic Network Team (http://www.alparray.ethz.ch/en/seismic_network/backbone/data-policy-and-citation/) and the permanent seismic networks used in this study (FR, IV, and MN). Figures were created using Generic Mapping Tools version 6 (Wessel et al., 2019) and Inkscape (www.inkscape.org).
275

Financial support

This research has been supported by the Deutsche Forschungsgemeinschaft (DFG), grant no. TH_2440/1-1, KO_2961/6-1, and LA_2970/4-1. The deployment of the French component of the AlpArray seismic network (AASN) was funded by the AlpArray-FR project of the Agence Nationale de la Recherche (contract ANR-15-CE31-0015).

280 Data availability

Data from the temporary and permanent land stations as well as the OBS are available through the AlpArray seismic network (Z3, http://data.datacite.org/10.12686/alparray/z3_2015), the Italian network (IV, <http://doi.org/10.13127/SD/X0FXnH7QfY>), the French RESIF-RLBP network (FR, <http://doi.org/10.15778/RESIF.FR>), and the Mediterranean MedNet network (MN, <https://doi.org/10.13127/SD/fBBBtDtd6q>).

285 Competing interests

The authors declare that they have no conflict of interest.

Author contributions

MT carried out data analysis and contributed to the manuscript. AD wrote the manuscript and contributed to the data analysis. AD and MT created the figures. IG contributed to the manuscript with in depth discussion and manuscript editing. HK was PI of the research cruise MSM71 with R/V Maria S. Merian. WC was PI of the AlpArray cruise with R/V Pourquoi Pas?. HK, DL, IG, MT, AP, WC acquired funding and planned the research concept. HK, AD, FP, MT, DL, AP participated in cruise MSM71 onboard R/V Maria S. Merian. WC, FP, AP deployed the AlpArray OBS network on board the R/V Pourquoi Pas?.

Team list

The complete member list of the AlpArray Working Group can be found at:
